Introduction

Bifurcation theory describes how the qualitative behavior of equilibria changes as a system parameter varies. Here we explore different types of bifurcations using R.

Required Libraries

```r
library(ggplot2)
```

---

1. Supercritical pitchfork bifurcation

1.1 Theoretical background

A **supercritical pitchfork bifurcation** occurs when a stable equilibrium splits into two new stable equilibria as the control parameter r crosses a critical value. The system under study is:

$$\dot{x} = r \cdot x - x^3$$

The fixed points of this system are:

$$x^* = 0, \quad \pm\sqrt{r}$$

The number and stability of fixed points depend on the value of r:

- **Case A**: $r < 0 \rightarrow$ Only one stable fixed point at $x = 0$.
- **Case B**: $r = 0 \rightarrow$ Bifurcation point where stability changes.
- **Case C**: $r > 0 \rightarrow$ The origin becomes unstable, and two new stable fixed points appear.

1.2 Phase portraits for different r

By plotting $\dot{x}$ versus x, we observe the change in stability of the origin $x^* = 0$. When $r = -1$, the origin is stable; when $r = 1$, it becomes unstable.

```r
supercritical_map <- function(x, r) {
  return(r * x - x^3)
}

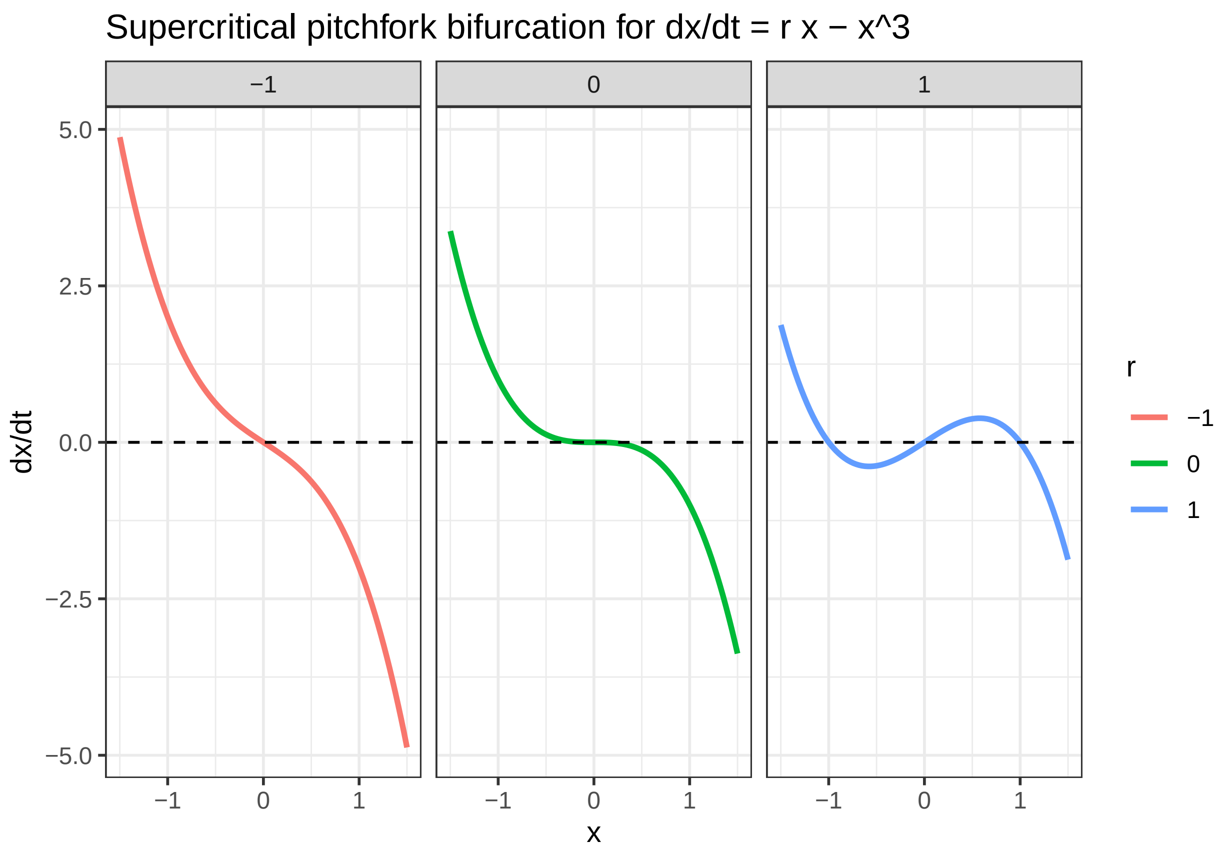
r_values <- c(-1,0,1)
x_vals <- seq(-1.5, 1.5, length.out = 100)
dx_dt_df <- NULL  # Initialize as empty data frame

for (r in r_values) {
  df_aux <- data.frame(
    x = x_vals,
    dx_dt = supercritical_map(x_vals, r),
    r = r)
  dx_dt_df <- rbind(dx_dt_df, df_aux)  # Append new rows

}

ggplot(data = dx_dt_df,
       aes(x = x, y = dx_dt, color = as.factor(r))) +
  geom_line(linewidth = 1) +
  geom_hline(yintercept = 0, linetype = "dashed") +
```

```
  labs(title = "Supercritical pitchfork bifurcation for dx/dt = r x - x^3",
       x = "x", y = "dx/dt", color = "r") +
  facet_grid(~r)+
  theme_bw()
```



1.3 Bifurcation diagram

To visualize how the nature of the roots depends on r, we plot the fixed points of the system against r, using colors to indicate stability:

- **Blue** = Stable equilibrium
- **Red** = Unstable equilibrium

```
supercritical_map <- function(x, r) {
  return(r * x - x^3)
}

fixed_points_supercritical <- function(r) {
  roots <- polyroot(c(0,r,0,-1))
  real_roots <- roots[round(Im(roots),10)==0]
  return(Re(real_roots))
}

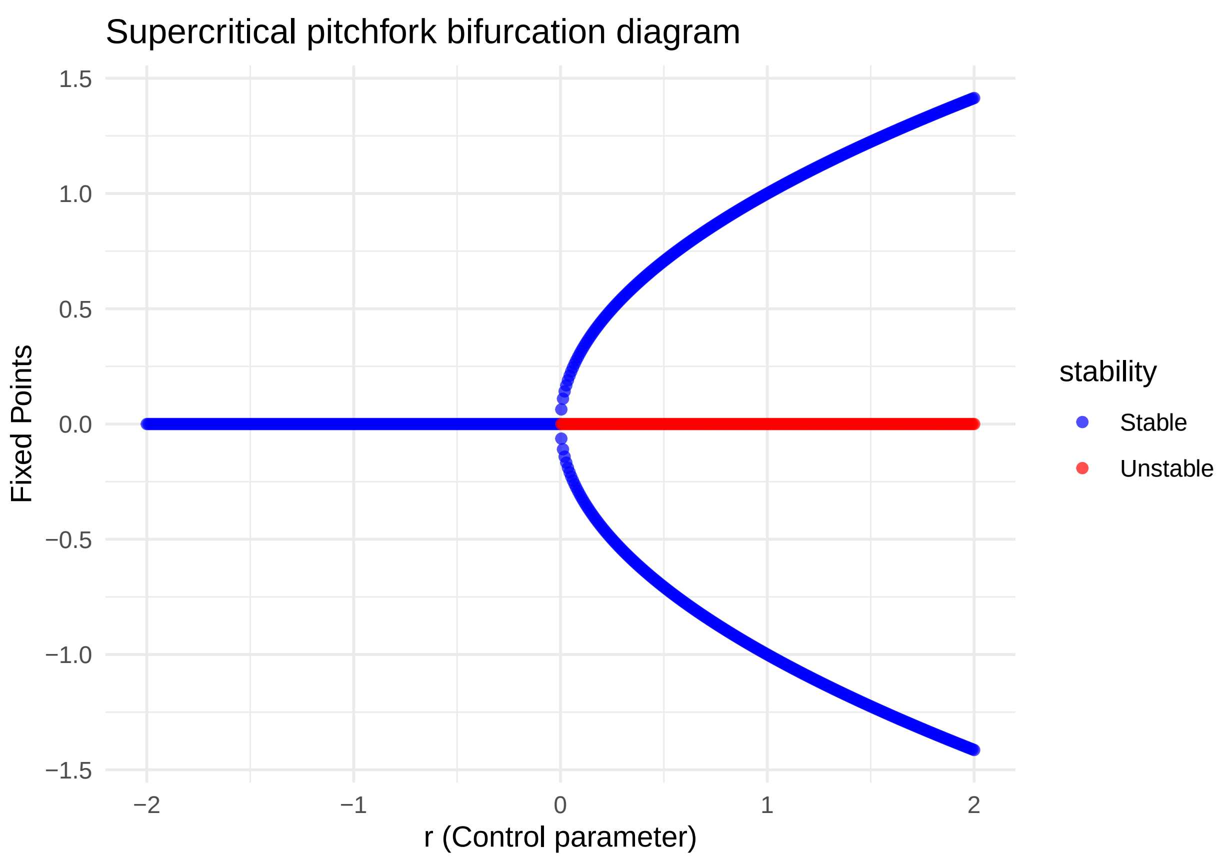
stability_supercritical <- function(x, r) {
```

```r
  derivative <- r - 3 * x^2
  if (derivative < 0) "Stable" else "Unstable"
}

r_values <- seq(-2, 2, length.out = 500)
bifurcation_data <- NULL #Empty variable to store bifurcation data

for (r in r_values) {
  points_super <- fixed_points_supercritical(r)
  for (x in points_super) {
    bifurcation_data <- rbind(bifurcation_data,
                              data.frame(r = r,
                                         x = x,
                                         stability = stability_supercritical(x, r)
                                         )
                              )
  }
}

ggplot(bifurcation_data, aes(x = r, y = x, color = stability)) +
  geom_point(size = 1.5, alpha = 0.7) +
  scale_color_manual(values = c("Stable" = "blue", "Unstable" = "red")) +
  labs(title = "Supercritical pitchfork bifurcation diagram",
       x = "r (Control parameter)", y = "Fixed Points") +
  theme_minimal()
```



2. Subcritical pitchfork bifurcation

2.1 Theoretical background

A **subcritical pitchfork bifurcation** is characterized by an unstable fixed point that merges with a stable one as the control parameter r changes. The system under study is:

$$\dot{x} = r \cdot x + x^3$$

The fixed points of this system are:

$$x^* = 0, \quad \pm\sqrt{-r}$$

2.2 Bifurcation diagram

To visualize how the nature of the roots depends on r, we plot the fixed points of the system against r, using colors to indicate stability:

- **Blue** = Stable equilibrium
- **Red** = Unstable equilibrium

```
subcritical_map <- function(x, r) {
  return(r * x + x^3)
}

fixed_points_subcritical <- function(r) {
  roots <- polyroot(c(0,r,0,1))
  real_roots <- roots[round(Im(roots),10)==0]
  return(Re(real_roots))
}

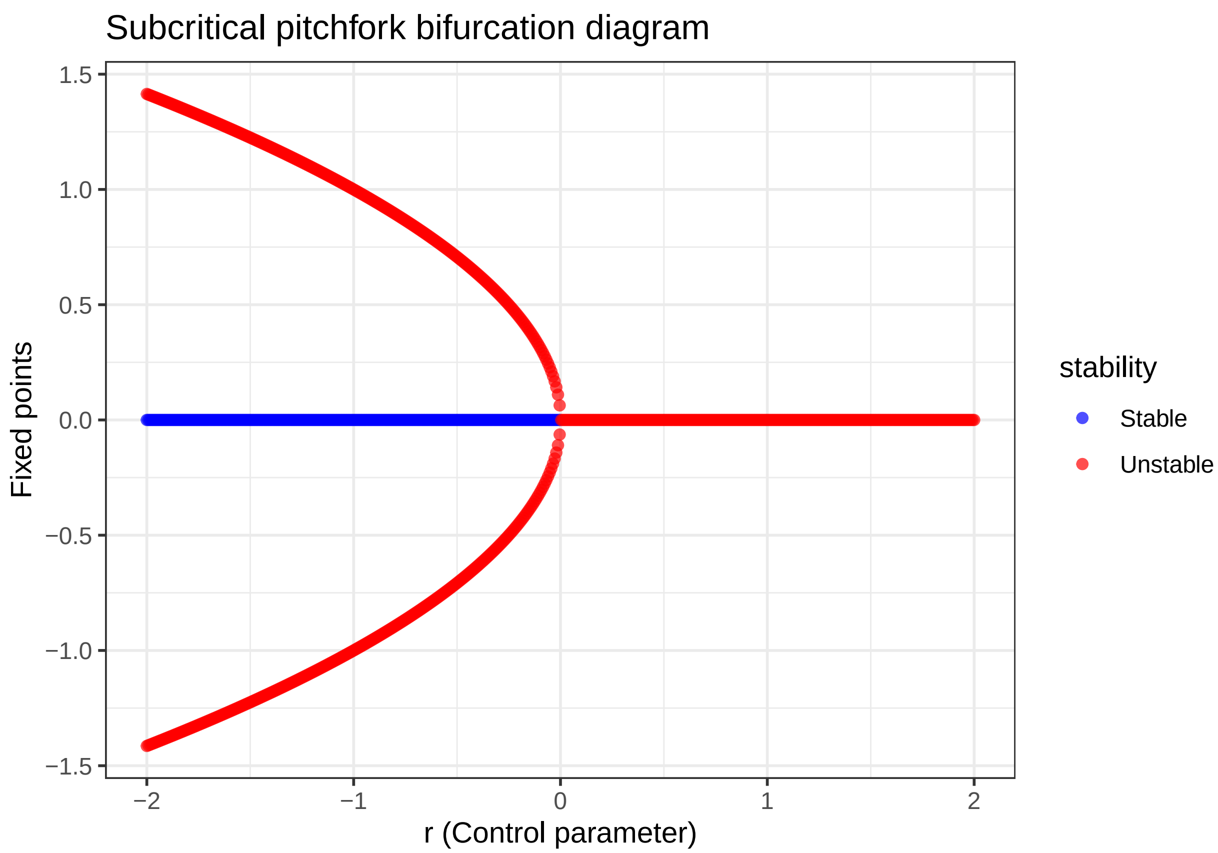
stability_subcritical <- function(x, r) {
  derivative <- r + 3 * x^2
  if (derivative < 0) "Stable" else "Unstable"
}

r_values <- seq(-2, 2, length.out = 500)
bifurcation_data <- NULL #Empty variable to store bifurcation data

for (r in r_values) {
  points_sub <- fixed_points_subcritical(r)
  for (x in points_sub) {
    bifurcation_data <- rbind(bifurcation_data,
                              data.frame(r = r,
                                         x = x,
                                         stability = stability_subcritical(x, r)
                                         )
                              )
```

```
  }
}

ggplot(bifurcation_data, aes(x = r, y = x, color = stability)) +
  geom_point(size = 1.5, alpha = 0.7) +
  scale_color_manual(values = c("Stable" = "blue", "Unstable" = "red")) +
  labs(title = "Subcritical pitchfork bifurcation diagram",
       x = "r (Control parameter)", y = "Fixed points") +
  theme_bw()
```



---

3. Saddle-Node bifurcation

3.1 Theoretical background

A **saddle-Node bifurcation** occurs when two fixed points (one stable and one unstable) collide and annihilate each other as the control parameter r crosses a critical value. Consider the system:

$$\dot{x} = r - x^2$$

The fixed points of this system are:

$$x^* \pm \sqrt{r}$$

Depending on the value of r:

- **Case A**: $r < 0 \to$ No real fixed points, so the system does not have equilibrium solutions..
- **Case B**: $r = 0 \to$ A single real fixed point at $x^* = 0$. This is the point at which two fixed points collide.
- **Case C**: $r > 0 \to$ Two real fixed points appear:$x^* = +\sqrt{r}$ and $x^* = -\sqrt{r}$. One will be stable, and the other unstable, reflecting the "saddle" (unstable) and "node" (stable) nature.

The stability can be determined by evaluating the derivative of the right-hand side:

$$\frac{d}{dt}(r - x^2) = -2 \cdot x$$

- If $-2 \cdot x < 0$, the fixed point is **stable**.
- If $-2 \cdot x > 0$, the fixed point is **unstable**.

3.2 Phase portraits for different r

Similar to the supercritical case, we can plot $\dot{x} = r - x^2$ as a function of x for representative values of r. Note how the number of intersections with $\dot{x} = 0$ changes from no intersection (when $r < 0$) to one intersection at $r = 0$, and two intersections (one stable, one unstable) when $r > 0$.

By plotting $\dot{x}$ versus x, we observe the change in stability of the origin $x^* = 0$. When $r = -1$, the origin is stable; when $r = 1$, it becomes unstable.

```r
# Phase portrait function
saddle_node_map <- function(x, r) {
  return(r - x^2)
}

# Choose representative values of r
r_values <- c(-0.5, 0, 1)
x_vals <- seq(-2, 2, length.out = 200)

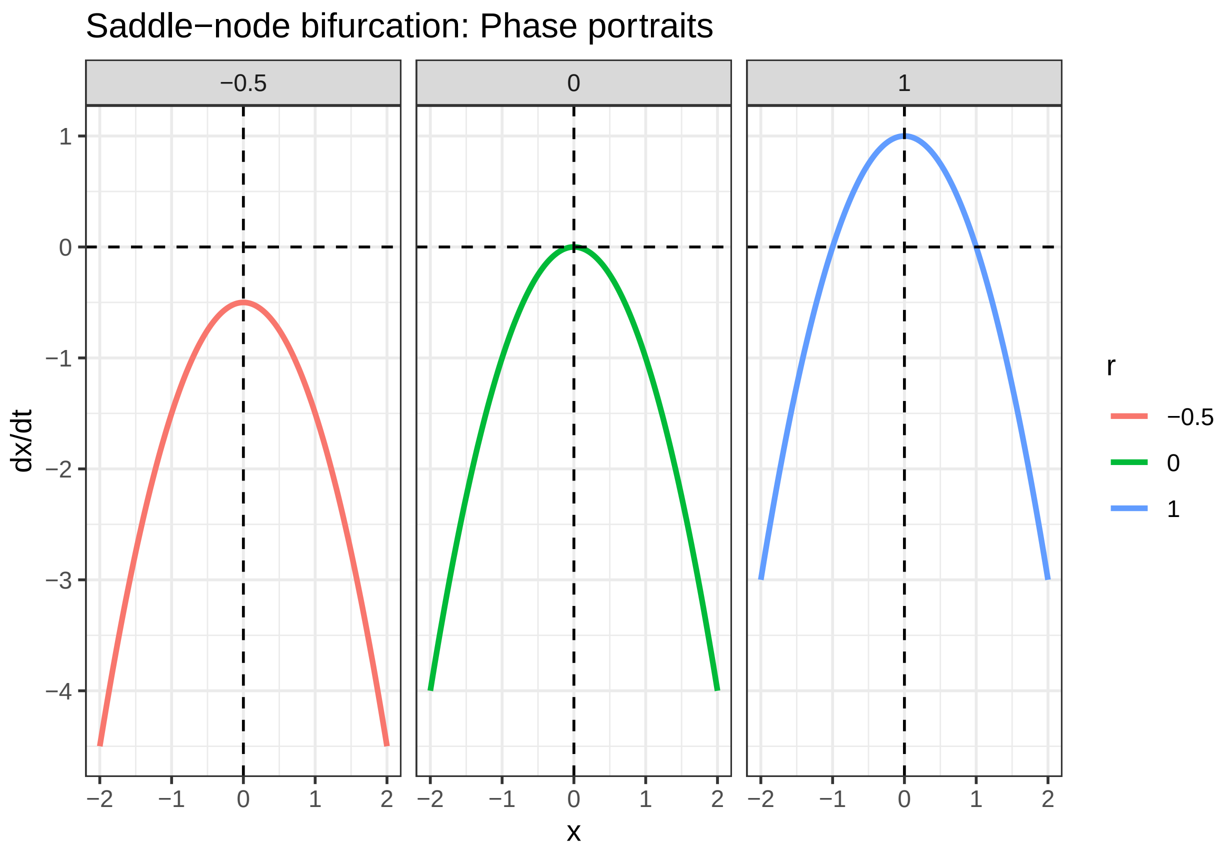
# Build data frame for plotting
df_phase <- data.frame()

for (r in r_values) {
  df_temp <- data.frame(
    x = x_vals,
    dx_dt = saddle_node_map(x_vals, r),
    r = as.factor(r)
  )
  df_phase <- rbind(df_phase, df_temp)
}

library(ggplot2)

ggplot(df_phase, aes(x = x, y = dx_dt, color = r)) +
```

```r
geom_line(linewidth = 1) +
geom_vline(xintercept = 0, linetype = "dashed") +
geom_hline(yintercept = 0, linetype = "dashed") +
labs(title = "Saddle-node bifurcation: Phase portraits",
     x = "x", y = "dx/dt", color = "r") +
facet_grid(~r) +
theme_bw()
```



- For $r = -0.5$, there are no real fixed points (the curve never crosses the horizontal line $\dot{x} = 0$.
- For $r = 0$, there is one real fixed point at $x = 0$ (the curve is tangent to the horizontal axis).
- For $r = 1$, there are two real fixed points, $x = \pm 1$. One is stable ($x < 0$ since $-2 \cdot x > 0$ there), and the other is unstable ($x > 0$ since since $-2 \cdot x < 0$ there).

3.3 Bifurcation diagram

Finally, we construct the bifurcation diagram by identifying the fixed points across a range of r values and coloring them according to their stability:

- **Blue** = Stable equilibrium
- **Red** = Unstable equilibrium

Notice how, for $r > 0$, two branches appear (stable and unstable), and for $r < 0$, there is no real fixed point.

```r
# map_function <- function(x, r) {
#   return(r - x^2)
# }

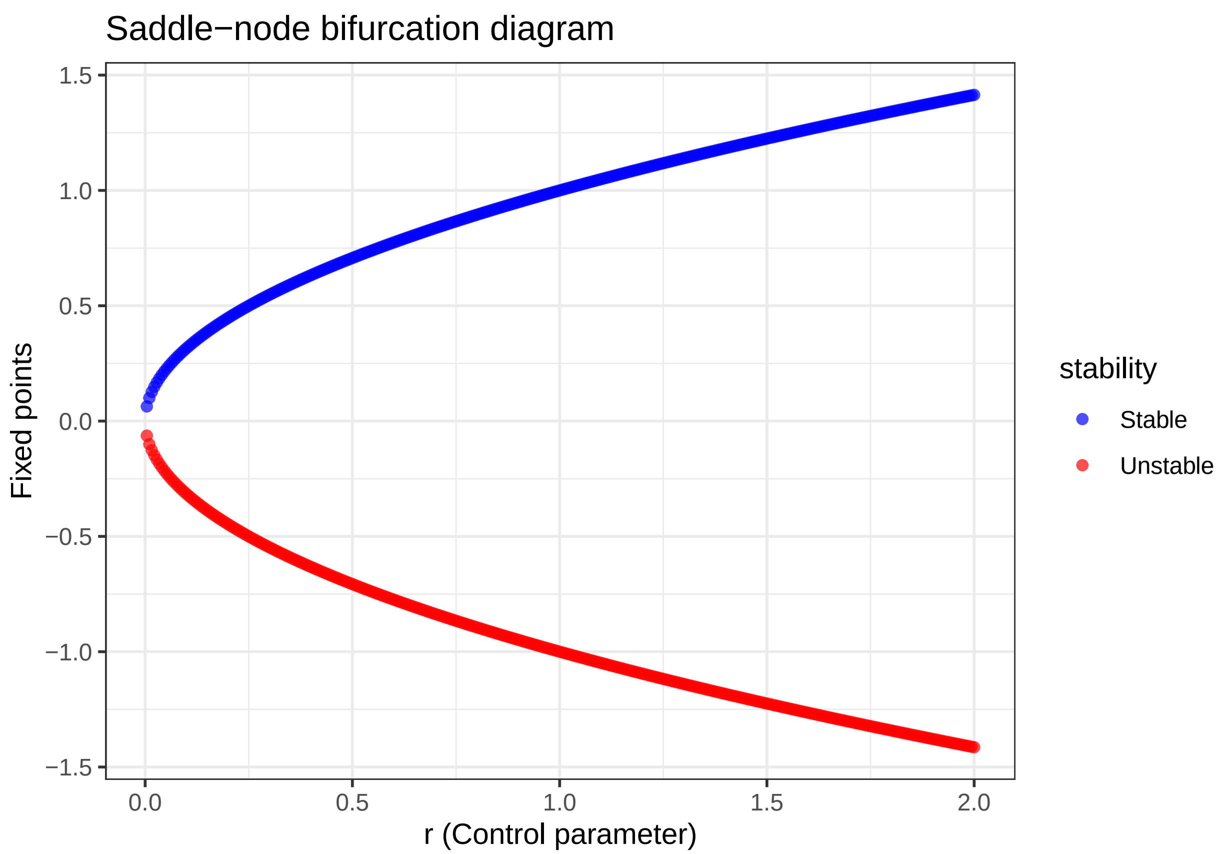
fixed_points_saddle_node <- function(r) {
  roots <- polyroot(c(r,0,-1))
  real_roots <- roots[round(Im(roots),10)==0]
  return(Re(real_roots))
}

stability_saddle_node <- function(x, r) {
  derivative <- -2 * x
  if (derivative < 0) "Stable" else "Unstable"
}

r_values <- seq(-1, 2, length.out = 500)
bifurcation_data <- NULL #Empty variable to store bifurcation data

for (r in r_values) {
  points <- fixed_points_saddle_node(r)
  for (x in points) {
    bifurcation_data <- rbind(bifurcation_data,
                              data.frame(r = r,
                                         x = x,
                                         stability = stability_saddle_node(x, r)
                                         )
                              )
  }
}

ggplot(bifurcation_data, aes(x = r, y = x, color = stability)) +
  geom_point(size = 1.5, alpha = 0.7) +
  scale_color_manual(values = c("Stable" = "blue", "Unstable" = "red")) +
  labs(title = "Saddle-node bifurcation diagram",
       x = "r (Control parameter)", y = "Fixed points") +
  theme_bw()
```



---

4. Transcritical Bifurcation

4.1 Theoretical background

A **transcritical bifurcation** occurs when two fixed points exchange their stability as a parameter is varied. Unlike the saddle-node bifurcation, in the transcritical case both fixed points exist for all parameter values, but their stability changes at the critical point. Consider the system:

Consider the system:

$$\dot{x} = rx - x^2$$

This system has two fixed points:

- $x^* = 0$
- $x^* = r$

The stability of fixed points depend on the value of r:

- At $x^* = 0$: $\frac{d}{dx}(rx - x^2)\big|_{x^*=0} = r$
- At $x^* = r$: $\frac{d}{dx}(rx - x^2)\big|_{x^*=r} = -r$

Therefore:

- If $r < 0$, $x^* = 0$ is stable and $x^* = r$ is unstable.
- If $r > 0$, $x^* = 0$ is unstable and $x^* = r$ is stable.
- At $r = 0$, both fixed points coincide and exchange stability.

4.2 Phase portraits for different r

By plotting $\dot{x}$ versus x, we observe the change in stability of the fixed points $x^* = 0$ and $x^* = r$. When $r = -1$, the origin is stable; when $r = 1$, the roles are reversed: the origin becomes unstable and the other fixed point is stable.

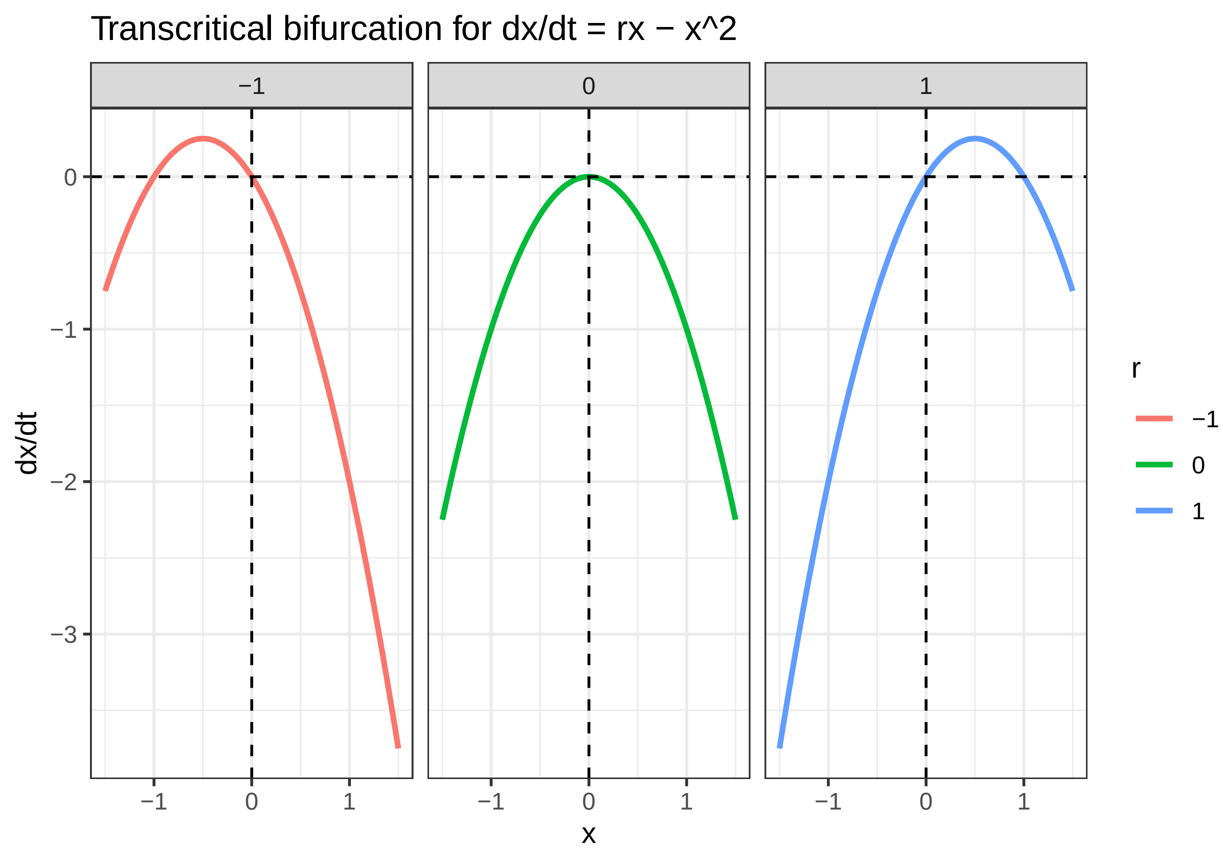
```r
transcritical_map <- function(x, r) {
  return(r*x  - x^2)
}

r_values <- c(-1,0,1)
x_vals <- seq(-1.5, 1.5, length.out = 100)
dx_dt_df <- NULL  # Initialize as empty data frame

for (r in r_values) {
  df_aux <- data.frame(
    x = x_vals,
    dx_dt = transcritical_map(x_vals, r),
    r = r)
  dx_dt_df <- rbind(dx_dt_df, df_aux)  # Append new rows

}

ggplot(data = dx_dt_df,
       aes(x = x, y = dx_dt, color = as.factor(r))) +
  geom_line(linewidth = 1) +
  geom_vline(xintercept = 0, linetype = "dashed") +
  geom_hline(yintercept = 0, linetype = "dashed") +
  labs(title = "Transcritical bifurcation for dx/dt = rx - x^2",
       x = "x", y = "dx/dt", color = "r") +
  facet_grid(~r)+
  theme_bw()
```



4.3 Bifurcation diagram

Finally, we build the bifurcation diagram by tracking the fixed points as the parameter r varies, and we color-code them based on their stability:

- **Blue** = Stable equilibrium
- **Red** = Unstable equilibrium

```
# map_function <- function(x, r) {
#   return(r*x - x^2)
# }

fixed_points_transcritical_map <- function(r) {
  roots <- polyroot(c(0,r,-1))
  real_roots <- roots[round(Im(roots),10)==0]
  return(Re(real_roots))
}

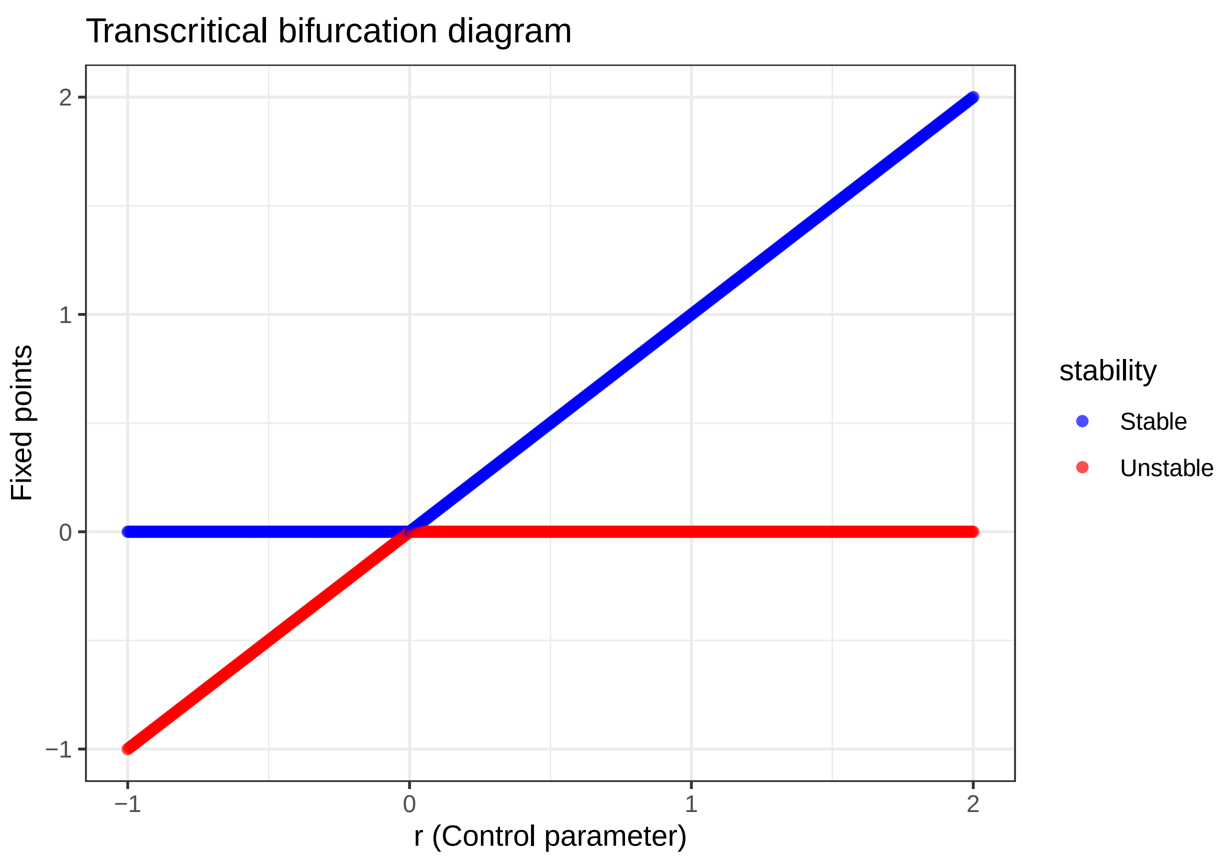
stability_transcritical_map <- function(x, r) {
  derivative <- r -2 * x
  if (derivative < 0) "Stable" else "Unstable"
}

r_values <- seq(-1, 2, length.out = 500)
```

```r
bifurcation_data <- NULL #Empty variable to store bifurcation data

for (r in r_values) {
  points <- fixed_points_transcritical_map(r)
  for (x in points) {
    bifurcation_data <- rbind(bifurcation_data,
                              data.frame(r = r,
                                         x = x,
                                         stability = stability_transcritical_map(x, r)
                                         )
                              )
  }
}

ggplot(bifurcation_data, aes(x = r, y = x, color = stability)) +
  geom_point(size = 1.5, alpha = 0.7) +
  scale_color_manual(values = c("Stable" = "blue", "Unstable" = "red")) +
  labs(title = "Transcritical bifurcation diagram",
       x = "r (Control parameter)", y = "Fixed points") +
  theme_bw()
```



Exercise

This pactice exercise is focused on characterizing the **subcritical pitchfork bifurcation** of the system:

$$\dot{x} = r\,x + x^3 - x^5.$$

1. **Find the Equilibrium Points**
   - Write down the equilibrium equation $\dot{x} = 0$.
   - Factorize the polynomial to identify the solutions for x and see how they depend on r.
2. **Stability Analysis**
   - For each equilibrium x^*, compute the derivative $\frac{d}{dx}(r\,x + x^3 - x^5) = r + 3x^2 - 5x^4$.
   - Conclude whether the equilibrium is **stable** (derivative < 0) or **unstable** (derivative > 0).
3. **Sketch Phase Portraits**
   - Choose representative values of r (negative, zero, positive).
   - Plot $\dot{x}$ vs. x in R, identify where $\dot{x} = 0$, and mark equilibria as stable or unstable.
4. **Numerical Bifurcation Diagram**
   - Adapt or run the R script above, which uses polynomial root-finding (`polyroot`) to locate equilibria.
   - Color them by stability and plot them against r.
5. **Interpret the Results**
   - Identify the critical parameter value(s) of r that cause a subcritical pitchfork bifurcation.
   - Compare to the simpler subcritical system $\dot{x} = r\,x + x^3$ to see how the additional $-x^5$ term changes the bifurcation structure.
